Abstract. Astrophysical fluids are generically turbulent, which means that frozen-in magnetic fields are, at least, weakly stochastic. Therefore realistic studies of astrophysical magnetic reconnection should include the effects of stochastic magnetic field. In the paper we discuss and test numerically the Lazarian & Vishniac (1999) model of magnetic field reconnection of weakly stochastic fields. The turbulence in the model is assumed to be subAlfvenic, with the magnetic field only slightly perturbed. The model predicts that the degree of magnetic field stochasticity controls the reconnection rate and that the reconnection can be fast independently on the presence or absence of anomalous plasma effects. For testing of the model we use 3D MHD simulations. To measure the reconnection rate we employ both the inflow of magnetic flux and a more sophisticated measure that we introduce in the paper. Both measures of reconnection provide consistent results. Our testing successfully reproduces the dependences predicted by the model, including the variations of the reconnection speed with the variations of the injection scale of turbulence driving as well as the intensity of driving. We conclude that, while anomalous and Hall-MHD effects in particular circumstances may be important for the initiation of reconnection, the generic astrophysical reconnection is fast due to turbulence, irrespectively of the microphysical plasma effects involved. This conclusion justifies numerical modeling of many astrophysical environments, e.g. interstellar medium, for which plasma-effect-based collisionless reconnection is not applicable.

1. Reconnection of Weakly Stochastic Magnetic Field

Magnetic reconnection is a fundamental problem of astrophysical MHD (see e.g., Priest & Forbes 2000 and references therein). Indeed, while the condition of magnetic field being frozen is well satisfied in the bulk of astrophysical plasma, one should wonder what happens when magnetic flux tubes try to push through each other. This is a very important question. For instance, the commonly employed *dynamo* theory allows a large-scale magnetic field to grow exponentially at the expense of small-scale turbulent energy. However, it has been known for some time that the back reaction of the field can suppress magnetic diffusion and defeat the dynamo. Indeed, if a parcel of fluid is threaded by a field loop in equipartition with the turbulence, the loop acts like a rubber band returning the parcel to its origin. As a result, small-scale magnetic fields accumulate most of the energy, while the mean magnetic field saturates far below equipartition with the surrounding fluid. To enable free motions of the fluid parcels, as re-

quired by the mean field dynamo, there should be a mechanism for cutting the "rubber bands". This mechanism is magnetic reconnection. Unfortunately, if reconnection happens at the rate allowed by generally accepted Sweet-Parker model (Parker 1957, Sweet 1958), it is far too slow. Turbulence would cause many magnetic reversals per parsec within the interstellar medium. Observations, on the contrary, show that magnetic field is coherent over the scales of hundreds of parsecs. This fact, as well as direct observations of Solar flares (which are generally accepted to be fed by reconnection), suggest that the rate of reconnection is many orders of magnitude more rapid than the Sweet-Parker theory suggests.

In general, if the reconnection were slow, the change of magnetic topology did not happen and the interacting flux tubes would create knots, redistributing magnetic energy to small scales. This is the expected outcome for the Sweet-Parker reconnection, which is extremely slow and inadequate for nearly all astrophysical situations.

Petscheck (1964) reconnection is an attempt to remedy the problem assuming that magnetic flux tubes get into contact over areas determined by microphysics and the reconnection regions open up. So far, the feasibility of Petscheck reconnection has been demonstrated in very restricted circumstances (see Shay & Drake 1998), which, for instance, exclude interstellar medium and other important astrophysical environments like stars and many types of accretion disks. One of the sources of these restrictions arises from the requirement that the medium should be collisionless in a very special sense, namely, that the extension of the current sheet should not exceed several dozens of electron mean free paths (see Yamada et al. 2006).

Lazarian & Vishniac (1999, henceforth LV99) proposed a model that naturally generalizes Sweet-Parker reconnection scheme for weakly turbulent magnetic fields. LV99 consider the case in which there exists a large scale, well-ordered magnetic field, of the kind that is normally used as a starting point for discussions of reconnection[1] (see Fig. 1). The difference with the Sweet-Parker reconnection arises both from the fact that in 3D generic configuration (note that 3D is essential and the effect of fast reconnection is absent in 2D) many independent patches of magnetic field get into contact and undergo reconnection. In addition, the outflow of plasma and shared magnetic flux happens not over a microscopically narrow region determined by Ohmic diffusion, but through a substantially wider region determined by field wandering. LV99 showed that magnetic reconnection gets fast when these two effects are taken into account. In fact, the LV99 reconnection rate is

$$V_{rec} = V_A \min\left[\left(\frac{L}{l}\right)^{1/2}, \left(\frac{l}{L}\right)^{1/2}\right]\left(\frac{V_l}{V_A}\right)^{1/2}, \qquad (1)$$

where V_A is the Alfvén speed, L is the size of the system, l is the injection scale, and V_l is the velocity amplitude at the injection scale. In this relation, the

[1]The LV99 model has nothing to do with the concept of turbulent magnetic diffusivity, which by some authors to justify the mean field dynamo. The latter concept requires bending of magnetic fields on very small scales, which is prohibited on energetic grounds for any dynamically important field.

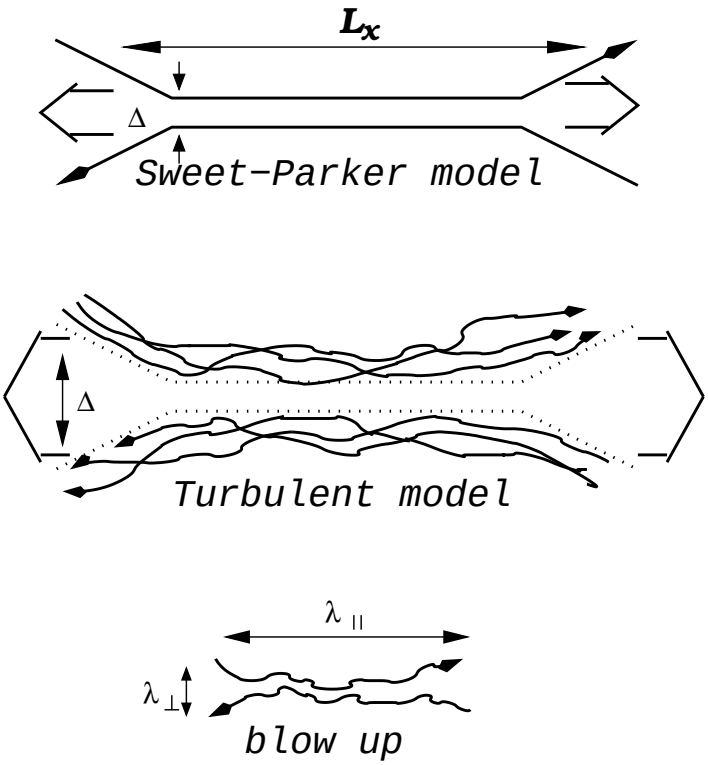

Figure 1. *Upper plot*: Sweet-Parker model of reconnection. The outflow is limited by a thin slot Δ, which is determined by Ohmic diffusivity. The other scale is an astrophysical scale $L \gg \Delta$. *Middle plot*: Reconnection of weakly stochastic magnetic field according to LV99. The model that accounts for the stochasticity of magnetic field lines. The outflow is limited by the diffusion of magnetic field lines, which depends on field line stochasticity. *Low plot*: An individual small scale reconnection region. The reconnection over small patches of magnetic field determines the local reconnection rate. The global reconnection rate is substantially larger as many independent patches come together.

reconnection speed is determined by the characteristics of turbulence, namely, its strength and injection scale. Most importantly, this rate is determined by magnetic field wandering and contains no explicit dependence on the Ohmic or anomalous resistivity. For isotropic injection of energy when the injection velocity is less than V_A the injection power P_{inj} is proportional to V_l^4 (see LV99), which means that Eq. (refeq:constraint) predicts $V_{rec} \sim P_{inj}^{1/2} l^{1/2}$, assuming that $l < L$. This is the dependence that we are testing in the paper.

Within this short paper we do not have space to discuss in detail neither LV99 model nor other approaches to reconnection attempted through years by various reseachers. More on these issues can be found in the paper by Lazarian & Vishniac (11), where also the implications of the LV99 model of reconnection are also discussed. We instead concentrate here on numerical testing of the model. The initial numerical testing of LV99 model is presented in (9), where the reconnection rate was measured as the inflow rate of unreconnected flux. Here we

present a more sophisticated and more theory-justified approach to measuring of the reconnection rate and compare the results of the two approaches.

2. Numerical Modeling of LV99 Reconnection

We use a higher-order shock-capturing Godunov-type scheme based on the essentially non oscillatory (ENO) spacial reconstruction and Runge-Kutta (RK) time integration (see 5, e.g.) to solve isothermal non-ideal MHD equations,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{v}) = 0, \tag{2}$$

$$\frac{\partial \rho \boldsymbol{v}}{\partial t} + \nabla \cdot \left[\rho \boldsymbol{v}\boldsymbol{v} + p_T I - \frac{\boldsymbol{B}\boldsymbol{B}}{4\pi} \right] = \boldsymbol{f}, \tag{3}$$

$$\frac{\partial \boldsymbol{A}}{\partial t} + \boldsymbol{E} = 0, \tag{4}$$

where ρ and $\boldsymbol{v}$ are plasma density and velocity, respectively, $\boldsymbol{A}$ is vector potential, $\boldsymbol{E} = -\boldsymbol{v} \times \boldsymbol{B} + \eta \boldsymbol{j}$ is electric field, $\boldsymbol{B} \equiv \nabla \times \boldsymbol{A}$ is magnetic field, $\boldsymbol{j} = \nabla \times \boldsymbol{B}$ is current density, $p_T = a^2\rho + B^2/8\pi$ is the total pressure, a is the isothermal speed of sound, η is resistivity coefficient, and $\boldsymbol{f}$ represents the forcing term. We incorporated the field interpolated constrained transport (CT) scheme (see 16) in to the integration of the induction equation to maintain the $\nabla \cdot \boldsymbol{B} = 0$ constraint numerically.

Our initial magnetic field is a Harris current sheet of the form $B_x = B_{x0} \tanh(y/\theta)$ with $B_{x0} = 1$. We use a uniform shear component $B_z = B_{z0} =$ const which varies between 0.0 and 1.0 depending in the model. The initial setup is completed by setting the density profile from the condition of the uniform total pressure $p_T(t = 0) =$ const and setting the initial velocity to zero everywhere. The speed of sound is set to 4. In order to study the resistivity dependence on the reconnection we vary the resistivity coefficient η between values $0.5 \cdot 10^{-4}$ and $2 \cdot 10^{-3}$ which are expressed in dimensionless units. This means that the velocity is expressed in units of Alfvén speed and time in units of Alfvén time $t_A = L/V_A$, where L is the size of the box. We initiate the magnetic reconnection using a small perturbation of vector potential $\delta A_z = B_{x0} \cos(2\pi x) \exp[-(y/d)^2]$ to the initial configuration of $A_z(t = 0)$. The parameter d describes the thickness of the perturbed region.

Numerical model of the LV99 reconnection is evolved in a box with open boundary conditions which we describe in the next sub-section. The box has sizes $L_x = L_z = 1$ and $L_y = 2$ with the resolution 256x512x256. It is extended in Y-direction in order to move the inflow boundaries far from the injection region. This minimizes the influence of the injected turbulence on the inflow.

In our model we drive turbulence using a method described by Alvelius (1). It is implemented in spectral space. The input energy is concentrated with a Gaussian profile around a wave vector corresponding to the injection scale l_{inj}. The randomness in the time makes the force neutral in the sense that it does not directly correlate with any of the time scales of the turbulent flow and it also makes the power input determined solely by the force-force correlation. The driving is completely solenoidal, which means that it does not produce density fluctuations.

3. Reconnection Rate Measures

One can measure the reconnection rate by averaging the inflow velocity V_{in} divided by the Alfvén speed V_A over the inflow boundaries. In this way our definition of the reconnection rate is

$$V_{rec} = \langle V_{in}/V_A \rangle_S = \int_{y=y_{min},y_{max}} \frac{\vec{V}}{V_A} \cdot d\vec{S}, \tag{5}$$

where S defines the XZ planes of the inflow boundaries. This measure is the most natural definition of the reconnection rate in the case of the laminar reconnection (Petscheck or Sweet-Parker ones). In the presence of turbulence, however, we could face an uncertainty arising from the fact that the turbulence driven in the center of the box, can remove inflow magnetic flux before it reaches the diffusion region and undergo the reconnection process. Whether or not this effect is important we may test only by using a different measure that takes the loss of unreconnected flux into account.

Our basic approach is to start by considering a conserved quantity, the magnetic flux Φ. First, we consider the flux contained within a plane inside the simulation volume. If $\hat{x}$ is the direction of the reconnecting field, then we start by considering the time change of the net flux of B_x. It is

$$\partial_t \Phi = \oint \boldsymbol{E} \cdot d\boldsymbol{l} = \oint (\boldsymbol{v} \times \boldsymbol{B} - \eta \boldsymbol{j}) \cdot d\boldsymbol{l} \tag{6}$$

If we evaluate the difference between the two sides we will find that it is not zero. Here, the resistivity η has to be included. Now we split the area of integration into two pieces, A_+ and A_-, defined by the sign of B_x. The fluxes have different sign, thus to consider the reconnection, which decreases the absolute value of magnetic flux, we have to subtract them, i.e.

$$\partial_t \Phi_+ - \partial_t \Phi_- = \partial_t \int |B_x| dA, \tag{7}$$

which we can write explicitly in terms of line integrals around A_+ and A_-

$$\partial_t \left[\int |B_x| dA \right] = \oint \boldsymbol{E} \cdot d\boldsymbol{l}_+ - \oint \boldsymbol{E} \cdot d\boldsymbol{l}_- = \oint \mathrm{sign}(B_x) \boldsymbol{E} \cdot d\boldsymbol{l} + \int 2\boldsymbol{E} \cdot d\boldsymbol{l}_{\mathrm{interface}}, \tag{8}$$

where $\boldsymbol{l}_{\mathrm{interface}}$ is the line separating A_+ and A_-. The last term describes the mutual annihilation of positive and negative B_x along the line separating them. By definition, this is the reconnection rate. Note, that this includes the motion of already reconnected flux lines through the plane of integration. Rather than try to calculate it numerically we define the interface term as $-2V_{rec}|B_{x,\infty}|L_z$, where $|B_{x,\infty}|$ is the asymptotic absolute value of B_x, and L_z is the width of the box. We can then calculate the other terms which do not involve trying to find the interface and the parallel component of the electric field. The end result, which is the new measure of reconnection rate, is

$$V_{\mathrm{rec}} = \frac{1}{2|B_{x,\infty}|L_z} \left[\oint \mathrm{sign}(B_x) \boldsymbol{E} \cdot d\boldsymbol{l} - \partial_t \int |B_x| dA \right] \tag{9}$$

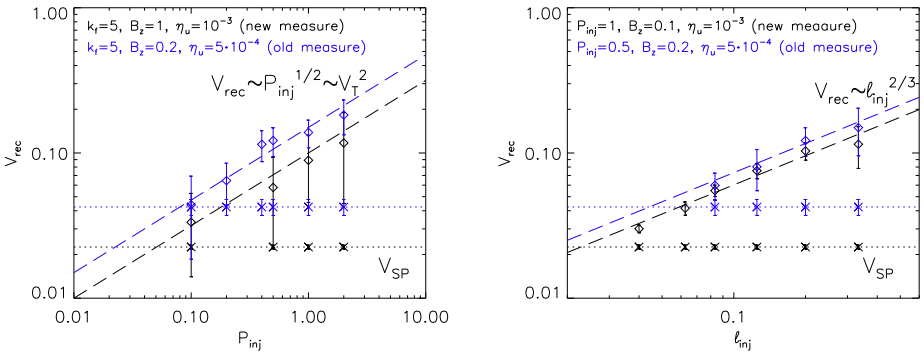

Figure 2. The comparison of the old and new measure of the reconnection rate. *Left Panel* The dependence of the reconnection rate V_{rec} on the power of turbulence P_{inj} (diamonds) using both approaches. The corresponding Sweet-Parker rates, without the presence of turbulence, are shown by x-symbols. *Right panel* The dependence of the reconnection rate V_{rec} on the injection scale l_{inj} (diamonds). Again, the Sweet-Parker rates are shown by x-symbols.

As one can note, this new reconnection measure contains the time derivative of the absolute value of B_x, and a number of boundary terms, such as advection of B_x across the boundary and the boundary integral of the resistive term $\eta \boldsymbol{j}$. The additional terms include all processes contributing the time change of $|B_x|$. More discussion of the measure of reconnection given by Eq. (9), as well as results of numerical calculations of the individual terms entering the equation is given in Kowal, Lazarian & Vishniac (2009).

4. Results

For the studies of the influence of turbulence on magnetic reconnection obtained in the three dimensional simulations of the magnetic reconnection with the measure given by Eq. (5) we refer our reader to (9). In this paper we compare the results obtained using the old and new measures, i.e. compare results obtained with Eqs. (5) and (9). We show particular examples of calculations obtained and defer a detailed parameter space study to Kowal et al. (2009) paper.

In Figure 2 we show the comparison of the dependencies of the reconnection rate obtained using old and new measure on the power of turbulence (left plot) and the injection scale (right plot). In the case of turbulent power dependency we used two different sets of models for each method. For the old method of V_{rec} estimation the shear component $B_z = 0.2$, the uniform resistivity $\eta = 5 \cdot 10^{-4}$. The injection scale is the same for both sets of models and $k_{inj} = 5$. Dashed lines show the LV99 dependence $V_{rec} \sim V_T^2$.

Both relations, using the old and new measures, show the same dependency, even though they were fitted to two different sets of models. It means, that the dependency of the reconnection rate is not sensitive to the strength of the shear

component B_z as well as it stays unmodified with the change of uniform resistivity and the numerical diffusivity of the method solving the MHD equations[2]

In the right plot of Figure 2 we show how the old and new measure of V_{rec} depends on the injection scale l_{inj}. Similarly to the dependence on the power of turbulence, this dependence does not change and in both cases is $V_{rec} \sim l_{inj}^{2/3}$, which is steeper than the $l^{1/2}$ rate predicted in LV99. However, LV99 assumed a very simple model of turbulence no energy at scales large than l, while in our numerical studies we observe an inverse cascade and the energy is present at scales larger than l. Therefore a steeper dependence that we observe is well justified.

Thus, the most important conclusion that we get from our study is that the two measures of reconnection rate agree and provide results consistent with the LV99 predictions. In Kowal et al. (2008) we showed that the reconnection of the magnetic field in presence of turbulence is independent of both anomalous and ordinary Ohmic resistivities.

5. Discussion

In this article we introduced a new way of measuring of reconnection rate and we tested the dependence of the LV99 reconnection rate on the injection power and the injection scale of MHD turbulence. We found that the old and new reconnection measures produce consistent results and both confirm the predictions of the LV99 reconnection model.

We note that the numerical testing of the LV99 reconnection model is far from trivial. The model is intrinsically three dimensional. In order to develop a turbulent cascade and minimize the role of numerical diffusion we have to use high resolution simulations. Another problem is the choice of proper boundary conditions. Our model requires open boundaries in order to allow the ejection of the reconnected flux. This property is crucial for the global reconnection constraint, since the reconnection stops when the outflow of the reconnected flux is blocked.

If the turbulence level increases, LV99 model predicts that this accelerates magnetic reconnection. At very low levels of turbulence, the width over which magnetic fields wander gets smaller than the thickness of the Sweet-Parker current sheet and the Sweet-Parker reconnection takes over.

The successful testing of LV99 model is good news for many areas of astrophysical numerical modeling. Unlike the models that rely on particular plasma properties to induce fast reconnection, the LV99 model is robust and fast in any type of fluid, provided that the fluid is, at least, weakly turbulent. If the fluid is laminar initially, the LV99 model predicts that such magnetic configurations should be prone to bursts of reconnection, when the outflow increases the level

[2]The observation that the old measure gives higher reconnection rate can be explained by the fact that the set of models for the old measure were calculated with a more dissipative code than the new set, which resulted in a higher value of numerical resistivity. Indeed, the Sweet-Parker reconnection speed depends on the resistivity, the resulting values of V_{rec} are higher.

of turbulence in the system. The latter may provide an appealing explanation of Solar Flares (see more in Lazarian & Vishniac 2008).

The LV99 model was used as a starting point for development of the model of reconnection of magnetic field in a partially ionized gas in Lazarian, Vishniac & Cho (2004). Although the latter model has to be tested, our successes in testing of LV99 model is an encouraging sign in terms of understanding of reconnection in partially ionized interstellar gases. The latter process can serve provide removal of magnetic field during star formation, for instance (cf. Shu et al. 2007).

Other important implications of the fast reconnection of the weakly stochastic field include the acceleration of cosmic rays as magnetic fields lines shrink as a result of reconnection (see de Gouveia dal Pino, E. & Lazarian, A. 2003, 2005). This process is similar to acceleration of energetic particles considered in a more restrictive case of collisionless Hall-MHD reconnection by Drake et al. (2006).
